B25ET1005 OOP, Practical-5

FAQ's.

1) What is function overloading?
→ It is a feature allowing multiple functions to share the name as long as their parameter lists differ.

2) Why is function overloading called compile-time polymorphism?
→ As the compiler resolves and selects the exact function to execute based on arguments during compilation hence function overloading is called compile-time polymorphism.

3) Can two functions be overloaded only by changing their return types?
→ No, because the compiler cannot determine the correct function based solely on the return type prior to the call.

4) What information does the compiler use to choose an overloaded function?
→ It uses the number, types and order of arguments provided at the call site.

5) How is function overloading different from function overriding?
→ Overloading occurs statically within the same scope with different parameters, whereas overriding occurs dynamically accross base &

derived classes.

6) Explain role of encapsulation in OOP. How is it achieved using classes?

→ Encapsulation wraps data & functions together into a class, using access specifiers like private & public to control visibility & protect internal state.
